DEAR READER,

Design thinking, a collaborative, human-focused approach to problem-solving, is no longer just for the creative industries. It has become an important management trend across many industries and has been embraced by many organizations. Its results are hard to ignore. Indeed, design-driven companies regularly outperform the S&P 500 by over 200 percent.¹

To date, the financial services industry has not led in adopting this approach. However, leaders are recognizing that important challenges, such as engaging with millennial customers, can be best addressed by using design thinking, through the methodology's exploratory approach, human focus, and bias towards action. This edition of the Journal examines the value of design thinking in financial services.

Design thinking introduces a fundamental cultural shift that places people at the heart of problem-solving, which is critical in a technology-driven environment. If the customer's real problems are not fully understood, technological solutions may fail to deliver the desired impact. In this context, design thinking offers a faster and more effective approach to innovation and strategic transformation.

The case studies and success stories in this edition showcase the true value of design thinking in the real world, and how this approach is an essential competitive tool for firms looking to outperform their peers in an increasingly innovation-driven and customer-centric future. At Mastercard, design thinking has become a part of almost all organizational initiatives, from product development, research and employee engagement to solving challenges with customers and partners. Meanwhile, at DBS Bank in Singapore, a data-informed design model has been firmly embedded into the bank's culture, enabling them to successfully move from being ranked last among peers for customer service in 2009, to being named the Best Bank in the World by Global Finance in 2018.

I hope that you enjoy the quality of the expertise and points of view on offer in this edition, and I wish you every success for the remainder of the year.

EARLY WARNING INDICATORS OF BANKING CRISES: EXPANDING THE FAMILY¹

IÑAKI ALDASORO | Economist, Monetary and Economic Department, BIS

CLAUDIO BORIO | Head of the Monetary and Economic Department, BIS

MATHIAS DREHMANN | Principal Economist, Monetary and Economic Department, BIS

ABSTRACT

Household and international debt (cross-border or in foreign currency) are a potential source of vulnerabilities that could eventually lead to banking crises. We explore this issue formally by assessing the performance of these debt categories as early warning indicators (EWIs) for systemic banking crises. We find that they do contain useful information. In fact, over the more recent subsample, for household and cross-border debt indicators the information is similar to that of the more commonly used aggregate credit variables regularly monitored by the Bank for International Settlements (BIS). Confirming previous work, combining these indicators with property prices improves performance. An analysis of current global conditions based on this richer information set points to the build-up of vulnerabilities in several countries.

1. INTRODUCTION

Early warning indicators (EWIs) of banking crises are typically based on the notion that crises take root in disruptive financial cycles. The basic intuition is that outside financial booms can generate the conditions for future banking distress. The narrative of financial booms is well understood: risk appetite is high, asset prices soar, and credit surges. Yet, it is difficult to detect the build-up of financial booms in real time and with reasonable confidence. It is here that EWIs come in. Many studies, including at the BIS, have found that one can identify such unsustainable booms reasonably well based on, say, deviations of credit and asset prices from long-run trends (gaps) breaching certain critical thresholds.

To detect the build-up of vulnerabilities around the globe, in recent years the BIS has regularly published credit-to-GDP gaps, economy-wide debt service ratios (DSRs), and, less frequently, property price gaps. While these aggregate indicators are useful, research has pointed to the importance of specific subcategories of debt as a source of vulnerabilities, especially household debt and cross-border and/or foreign currency debt (international debt for short).

Against this backdrop, in this article we do two things. First, we assess the EWI performance of both household and international debt. Here, we draw extensively on BIS statistics, notably the international banking and securities statistics as well as sectoral credit data and DSRs. Second, we map the statistical analysis into current conditions, taking into account also the information from aggregate indicators. In the process, we take the opportunity to clarify some common misconceptions about the interpretation of EWIs.

¹ The authors would like to thank Stefan Avdjiev, Stijn Claessens, Ben Cohen, Ingo Fender, Mikael Juselius, and Pat McGuire for helpful comments and Bat-el Berger, Anamaria Illes, Matthias Lörch, Kristina Micic, and Taejin Park for excellent research assistance. The views expressed in this article are those of the authors and do not necessarily reflect those of the BIS.

We come up with three main findings. First, indicators based on household and international, in particular cross-border, debt do contain useful information about future banking distress. The household sector DSRs perform especially well. Second, as might be expected, it is possible to further improve performance by combining individual indicators. Confirming previous work, we find that combining debt variables with property prices is especially helpful. Finally, the indicators currently point to the build-up of risks in several economies.

This article is structured as follows. The first section reviews the rationale behind EWIs and provides a first look at the behavior of selected candidate indicator variables around crises. The second formally evaluates their EWI performance. We first compare indicators on a standalone basis and then show the gains in predictive power from combining them. The third section draws on these findings to discuss current vulnerabilities. We also provide a short guide on how to interpret indicators. A final section concludes.

2. THE RATIONALE BEHIND EWIS

EWIs typically capture booms in the financial cycle in a stylized way. The notion of the financial cycle refers to the self-perpetuating sequence of financial expansions and contractions that can amplify business fluctuations

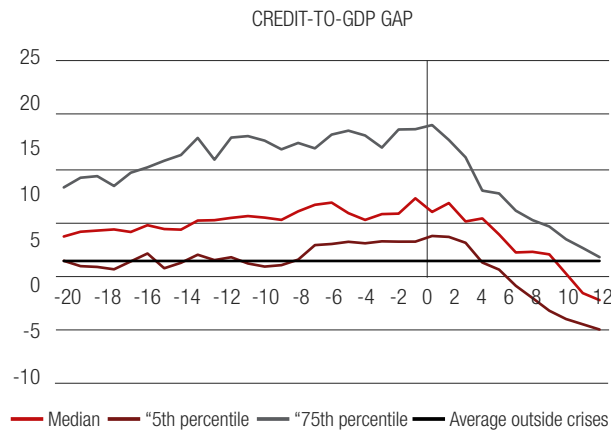

[Minsky (1982), Kindleberger (2000), Borio (2014)]. Further, outsized financial booms can lead to stress and even financial crises. While progress has been made, measuring the financial cycle remains challenging: the underlying theoretical modeling is scant and there is no single aggregate measure of financial activity. That said, a consensus has started to emerge that credit aggregates and asset prices, especially property prices, play an important role [Terrones et al. (2011), Drehmann et al. (2012)].

The existing BIS EWIs translate the intuitive notion of a financial boom into simple and transparent measures. The BIS has regularly published and monitored aggregate private sector credit-to-GDP gaps, residential property price gaps, and DSRs for the private non-financial sector. The credit-to-GDP gap is calculated as the difference between the credit-to-GDP ratio and its (one-sided) long-term trend.² Detrending is designed to remove the impact of benign, long-term changes in the underlying series; for example, those that result from financial development. The gap opens up if the increase in the credit-to-GDP ratio strongly outpaces the trend for some time, pointing to a possible financial imbalance. The property price gap is the equivalent measure, defined as the deviation of inflation-adjusted residential property prices from their trend. DSRs measure interest payments and amortizations relative to income.³ As high credit growth feeds into higher debt service down the road, DSRs rise during credit booms [Drehmann et al. (2017)]. And since they take into account interest payments, they could perform better than the credit gap or credit growth when debt builds up continuously but more slowly over time, making balance sheets vulnerable to increases in interest rates.

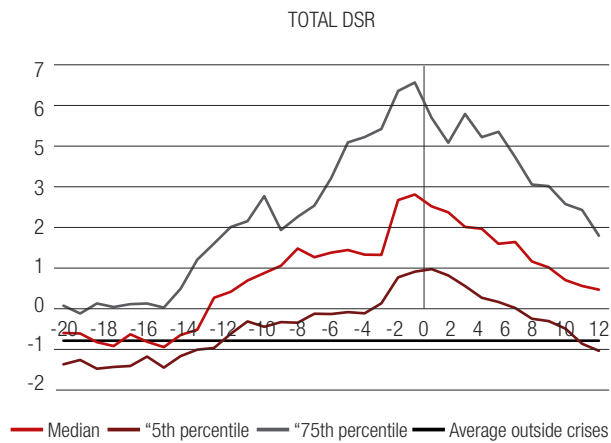

² The credit-to-GDP gap is the difference between the ratio of total non-financial sector credit to GDP and its trend based on a one-sided Hodrick-Prescott (HP) filter with the smoothing parameter equal to 400,000. Such a high value ensures a very slowly moving trend. The residential property price gap is the deviation of inflation-adjusted residential property prices from a similarly constructed trend. For a discussion of the appropriateness of this trend measure in this specific context, see Drehmann and Tsatsaronis (2014).

³ Since most countries do not compile data on amortization payments, these are estimated using information from debt maturities, interest rates, and outstanding debt stocks [Drehmann et al. (2015)].

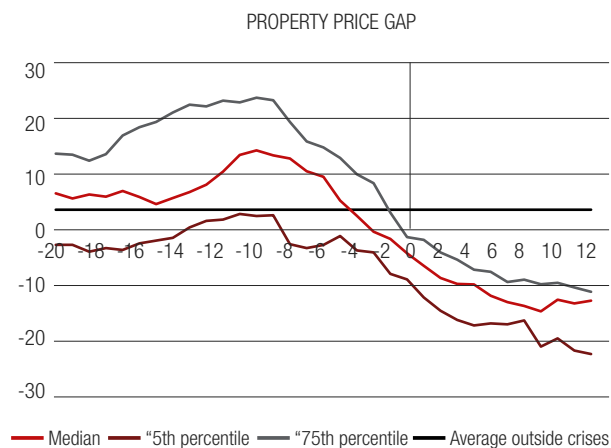

Figure 1: Evolution of existing BIS EWI variables around past banking crises

Difference of the credit-to-GDP ratio from its long-run trend computed with a one-sided HP filter.

Difference of the total DSR from country-specific 20-year rolling averages.

Deviation of real property prices from their long-run trend computed with a one-sided HP filter.

Note: The vertical line indicates time = 0. The historical dispersion (median, 25th, and 75th percentiles) of the relevant variable is taken at the specific quarter across all crisis episodes available for the respective indicator.

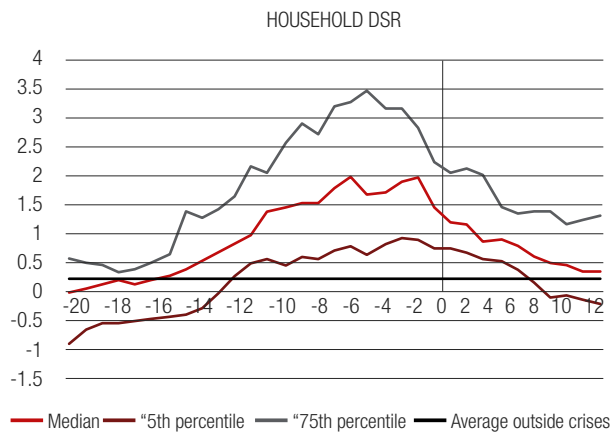

Sources: IMF, International Financial Statistics; national data; BIS credit to the non-financial sector and property price statistics; authors' calculations.

It is thus unsurprising that credit, DSRs, and property price gaps were comparatively high before past crises (Figure 1). For much the same reason, they perform well as EWIs on a standalone basis, and even better if combined [Borio and Lowe (2002a), Drehmann et al. (2011), Drehmann and Juselius (2012), Detken et al. (2014)].⁴

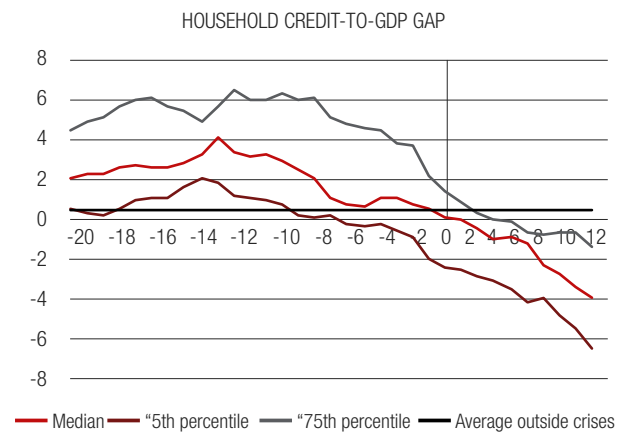

In addition to the aggregate credit developments covered by the current BIS EWIs, recent research has highlighted the importance of the household sector specifically.

While higher household debt boosts consumption and output growth in the short run, too much of it can lower output growth in the medium to long term [Mian et al. (2017), Lombardi et al. (2017), Zabai (2017)]. Excessive household debt has also been found to herald banking crises [Jordà et al. (2016), IMF (2017), Drehmann et al. (2017)]. As such, indicators assessing household debt developments feature prominently in many central bank financial stability reports [Bank of Canada (2017), ECB (2017), Bank of England (2017)].

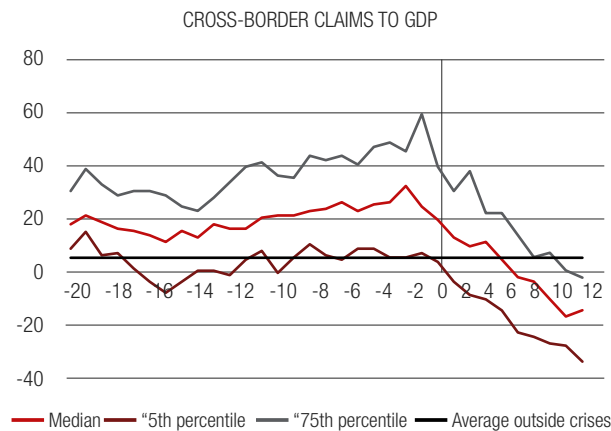

Figure 2: Evolution of new EWI variables around past banking crises

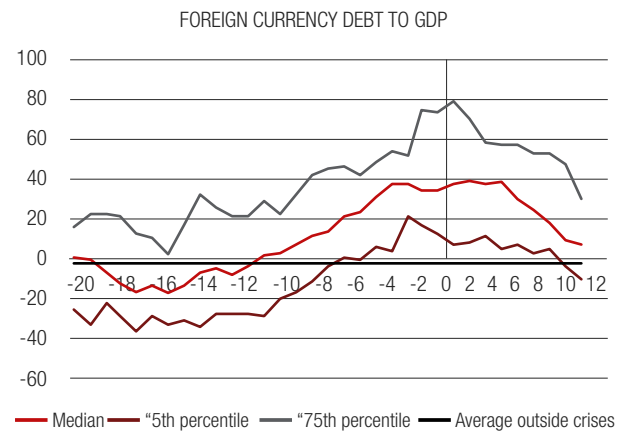

Difference of the household DSR from country-specific 20-year rolling averages.

Difference of the household credit-to-GDP ratio from its long-run trend computed with a one-sided HP filter.

Twelve-quarter growth rate in the cross-border claims-to-GDP ratio.

Twelve-quarter growth rate in the foreign currency debt-to-GDP ratio.

⁴ The credit gap was first proposed by Borio and Lowe (2002a), and the literature has found broadly similar EWI performance for slightly different measures, such as five-year growth rates in the credit-to-GDP ratio [Schularick and Taylor (2012)]. The credit-to-GDP gap has been incorporated into the policy process as the trigger variable for the imposition of a countercyclical capital buffer on supervised banks [BCBS (2010)].

Sources: IMF, International Financial Statistics; national data; BIS credit to the non-financial sector, debt securities, locational banking and property price statistics; authors' calculations.

Note: The vertical line indicates time = 0. The historical dispersion (median, 25th, and 75th, percentiles) of the relevant variable is taken at the specific quarter across all crisis episodes available for the respective indicator.

We consider two household sector indicators. The first is the household credit-to-GDP gap – an exact analogue of the total credit-to-GDP gap but using only credit to households in the numerator.⁵ The second is the difference between the household sector DSR and its 20-year rolling average [Drehmann et al. (2017)].⁶ By normalizing with a one-sided trend or a rolling average, we try to mimic the real-time environment policymakers face: the indicators are only based on past information, available at the time decisions are made.

Policymakers have also long focused on foreign currency and/or cross-border debt as a source of financial stability risks [Bruno and Shin (2015), Chui et al. (2014), BIS (2017), Borio et al. (2011), Avdjiev et al. (2012)]. In part, because of data limitations, the EW literature has operationalized this by looking at current account deficits [Lo Duca and Peltonen (2013)] or exchange rate developments [Borio and Lowe (2002b) and Gourinchas and Obstfeld (2012)].⁷

Drawing on the BIS international banking and debt statistics, we go one step further and explicitly evaluate cross-border borrowing, as well as foreign currency debt, issued across borders and at home. To normalize by country size and to tease out medium-term developments, we take the three-year growth rates in the corresponding ratios to GDP.⁸ The foreign currency debt is that of non-banks. For cross-border claims, we take a broader perspective that captures lending to non-banks and banks.⁹ We do so as indirect cross-border credit, i.e., cross-border credit that banks lend on to non-banks, is a frequent enabler of domestic credit expansions [Avdjiev et al. (2012)].¹⁰

Data coverage differs across indicators.¹¹ We have credit-to-GDP gaps and cross-border credit for 42 jurisdictions, often from the first quarter of 1980 to the second quarter of 2017.¹² Data are most limited for the household DSR, which is only available for 27 jurisdictions and often starts only in the mid-1990s. For crisis dating, we rely on the new European Systemic Risk Board crisis dataset [Lo Duca et al. (2017)] for European countries and on Drehmann et al. (2010) for the rest.¹³

A first glance at the data indicates that household debt may provide useful signals of the build-up of vulnerabilities (Figure 2). The household sector DSR (top row, left-hand panel) has been unusually high in the run-up to crises. The household credit-to-GDP gap (top row, right-hand panel) has also tended to be above normal levels during those phases.

The same holds for the international debt indicators (Figure 2, bottom row). The growth rate of the foreign currency debt-to-GDP ratio increases strongly pre-crisis, though it exhibits relatively high variation across countries (dashed lines). That of the cross-border debt-to-GDP ratio is also markedly higher but less variable.

⁵ We also assessed the three- or five-year growth rate of the household credit-to-GDP ratio. This did not have a statistically significantly different performance from the household credit-to-GDP gap.

⁶ As there are country-specific differences in the level, it is important to remove the long-run trend [Drehmann et al. (2015)].

⁷ We also considered exchange rates and current account balances as indicators. But as they underperformed cross-border credit indicators, we exclude them from the reported results.

⁸ Foreign currency debt is composed of the sum of US dollar-, euro-, yen-, sterling- and Swiss franc-denominated debt in the form of cross-border loans to non-banks, international debt securities issued by non-banks, and, where reported, local loans in foreign currency to non-banks. The series start in 1995, and we extend them backwards by applying the change in cross-border claims on non-banks from the BIS locational banking statistics. Our indicator on cross-border claims comprises lending in all instruments and currencies, to both banks and non-banks, as reported in the locational banking statistics. For both series we take the stocks and adjust them for breaks due to methodological or coverage changes. Given large breaks prior to 1984, we start from that point. (Available in the Online Appendix, obtainable from the authors).

⁹ In addition to the growth rate in the gross claims relative to GDP, we also assessed the performance of a corresponding net indicator (claims minus liabilities). This is likely to be a better measure of the credit that remains within the country. That said, this variable did not perform as well as its gross counterpart.

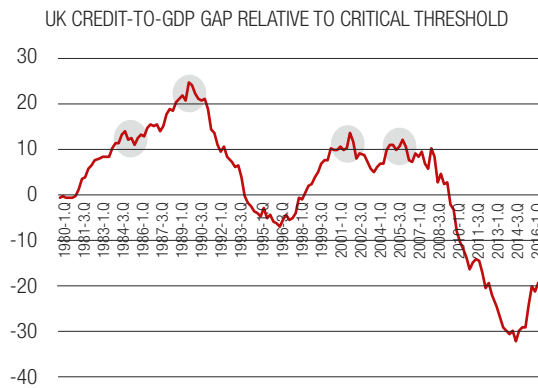

¹⁰ Indirect credit is not included in the foreign currency debt series as we would run into problems of double-counting. For instance, a bank may borrow in foreign currency from abroad to lend domestically (also in foreign currency).

¹¹ Coverage and sources are discussed in detail in the Online Appendix, available from the authors.

¹² Our broadest sample includes Argentina, Austria, Australia, Belgium, Brazil, Canada, Chile, China, Colombia, the Czech Republic, Denmark, Finland, France, Germany, Greece, Hong Kong SAR, Hungary, India, Indonesia, Ireland, Israel, Italy, Japan, Korea, Malaysia, Mexico, the Netherlands, Norway, New Zealand, Poland, Portugal, Russia, Saudi Arabia, Singapore, Spain, South Africa, Sweden, Switzerland, Thailand, Turkey, the United Kingdom, and the United States.

¹³ We exclude crises related to transitioning economies or that were imported from abroad based on Lo Duca et al. (2017). In addition, we classify the crisis in 2008 in Switzerland as imported. For the statistical analysis we drop post-crisis periods as identified in Lo Duca et al. (2017) and Laeven and Valencia (2012) for non-European countries.

Figure 3: Correct calls, false alarms, and the mapping between ROC curves and thresholds

The horizontal line at value 9 indicates the critical threshold for the credit-to-GDP gap obtained in Table 2. The shaded periods indicate the 12 quarters prior to crises – the prediction horizon. The black circles indicate periods in which the credit-to-GDP gap exceeded the critical threshold yet no crisis materialized within the prediction horizon. The red circles indicate periods in which the credit-to-GDP gap exceeded the critical threshold during the prediction horizon.

The horizontal line indicates a crisis prediction rate of 66%. The black crosses show the points on the ROC curves with the optimal noise-to-signal ratios. The green dotted line is the steepest line from the origin that touches a corner point on the portion of the ROC curve that is at or above the 66% prediction rate, identifying the point with the lowest noise-to-signal ratios.

Sources: IMF, International Financial Statistics; national data; BIS credit to the non-financial sector statistics; authors' calculations.

3. EVALUATING EWIS

When formally evaluating the performance of the EWIs, one would ideally like to know how policymakers assess the trade-off between missed crisis calls (type I errors) and false alarms (type II errors). However, this cannot be done with any precision, not least due to the limited experience from which to estimate expected costs and benefits [CGFS (2012)].

Absent well specified trade-offs, one way to assess the performance of EWIs is to consider the full mapping between type I and type II errors. This mapping is called the receiver operating characteristic (ROC) curve (see Section 3.1 for details). The area under the curve (AUC) is a convenient and interpretable summary measure of the signaling quality of a binary (yes/no) signal. A completely uninformative indicator has an AUC of 0.5. Correspondingly, the AUC for the perfect indicator equals 1. The AUC of an informative indicator falls in between and is statistically different from 0.5.

The AUC is a useful starting point, but it does not provide any information about the critical thresholds that, if breached, should raise concerns about financial stability risks. These ultimately depend on policymakers' preferences. To derive the thresholds, we assume that policymakers choose one that minimizes the noise-to-signal ratio (the ratio of false alarms to correctly predicted events) while capturing at least two-thirds of the crises, as in Borio and Drehmann (2009). (The section below discusses the link between this criterion and the ROC curve).

To be useful for policy, EWIs should not only have statistical forecasting power and rely on real-time information, but also satisfy three additional requirements [Drehmann and Juselius (2014)]: timing, stability, and ease of interpretation.

Having the right timing means that the indicators' signals should arrive early enough so that policy measures can be implemented and have an impact. That said, signals that arrive too early can be problematic [Caruana (2010)]. We focus on a 12-quarter forecast horizon.¹⁴ Employing a multi-year horizon also recognizes that the indicators may help identify the build-up of vulnerabilities, but cannot be expected to pinpoint the specific timing of a crisis.

¹⁴ Strictly speaking, one could drop the year that precedes the crisis on the grounds that by then it would be too late to take major preventive steps.

EWIs should also provide stable signals. Policymakers prefer to react to persistent movements, given the uncertainties involved. Stability requires that the forecast performance should not decrease as crises approach. This is a problem for residential property prices [Drehmann and Juselius (2012)], for which growth tends to slow or even become negative closer to crises (Figure 1, left-hand panel). This makes it hard to discern in real time whether the slowdown reflects the typical pre-crisis behavior of property prices or a welcome correction.

Finally, unless EWIs are easy to interpret intuitively their signals are likely to be ignored [Önkal et al. (2002), Lawrence et al. (2006)]. This is why our EWIs are simple, transparent, and based on the financial cycle logic. Their simple structure may also reduce the risk of overfitting associated with more sophisticated techniques.

3.1 Evaluating EWIs: ROC curves, noise-to-signal ratios and critical thresholds

It is possible to illustrate the trade-off between correct event predictions (as a share of all events) and false alarms (as a share of all normal periods) when choosing a threshold in the case of the credit-to-GDP gap for the United Kingdom (U.K.). The left-hand panel of Graph A shows the evolution of the gap since 1980. The shaded areas highlight the three years before the crises in 1991 and 2007, the period when we would like to see a signal based on the assumed three-year prediction horizon. The dashed red horizontal line indicates a credit-to-GDP gap of 9 – the optimal threshold given our analysis (Table 2). In both pre-crisis periods, the gap exceeded 9, so the prediction rate is 100% (red circles). Yet there are also false alarms (black circles). Increasing the threshold above 9 reduces the number of false calls. But once the threshold exceeds 11.5, the crisis in 2007 is no longer predicted, so that the prediction rate falls to 50%. Conversely, lowering the threshold from 9 does not increase the prediction rate and leads only to more false alarms.

The receiver operating characteristic (ROC) curve captures this trade-off between correct predictions and false alarms for all thresholds. For the U.K. the prediction rate can only be 100%, 50%, and 0% (Figure 3, top panel, blue line), with false alarm rates decreasing as the threshold increases. The solid red line depicts the ROC

curve for the credit-to-GDP gap based on all the available data in our sample. We can see that the credit-to-GDP gap is an informative indicator but is not perfect. For a perfect indicator we would find at least one threshold with a prediction rate of 100% and a false alarm rate of 0%. At the other end of the spectrum, a completely uninformative indicator would have an ROC curve that equaled the 45° line for every threshold, i.e., the same rate of correct and false calls.

The area under the ROC curve (AUC) provides a summary measure of the signaling quality of an indicator. Intuitively, it captures the average gain over the uninformed case (the 45° line) across all possible threshold combinations. The uninformative indicator has an AUC equal to 0.5 (i.e., the area under the 45° line equals 0.5), while that for the fully informative indicator is equal to 1. The intermediate cases have values in between.

While the ROC maps the full set of trade-offs, the policymaker may weigh missed crisis calls and false alarms differently. Unfortunately, these preferences are not known. As discussed in the main text, we therefore assume that policymakers choose a threshold that minimizes the noise-to-signal ratio (the ratio of false alarms to correctly predicted events), while capturing at least two-thirds of the crises.

It is possible to find the points on the ROC curve that correspond to the optimal thresholds for the U.K. and the more general case (black crosses). The U.K. case is especially intuitive. One picks the part of the ROC curve that identifies a prediction rate of at least 66% of crises – here the only possible one is 100%. Next one moves on that line as far as left as possible, thereby minimizing false alarms, i.e., one chooses the leftmost corner. The more general case is slightly more complicated, although the procedure is the same. One picks the steepest line from the origin (dotted green line) that touches a corner point on the portion of the ROC curve that is at or above the 66% prediction rate (red dashed line). This works because the slope of such a line equals the signal-to-noise ratio of the threshold associated with the corner point on the ROC curve. And as the signal-to-noise ratio is the inverse of the noise-to-signal ratio, the steepest line finds the point on the ROC curve with the lowest noise-to-signal ratio.

Table 1: A comparison of the predictive power of single EWIs using the AUC

4. STANDALONE INDICATORS

To evaluate and compare the performance of the indicators on a standalone basis, we proceed in two steps. Initially, to assess their general information content, we use the AUC criterion. We then evaluate the indicators from an operational perspective by analyzing optimal thresholds based on specific preferences.

We do so using two different samples: the full sample available for each indicator, and the much smaller common sample. The common sample allows a comparison of like with like, but it reduces our sample size considerably. We, therefore, also use the full sample available for each indicator as a comparison.

Although we try to collect as much data as possible, predicting crises inevitably means predicting rare events. Data coverage is best for the credit-to-GDP gap. But even then, we only cover 30 crises. The common sample covers 19 episodes, 12 of which are related to the Great Financial Crisis (GFC). In addition, the dataset is tilted towards advanced economies. Thus, the use of the full sample available for each indicator is important for robustness. For brevity, we only report this for the threshold analysis. In addition, we did robustness checks, not reported here, running the statistical tests on pre- and post-2000 subsamples to ensure that the GFC

does not drive the results. While all these robustness checks underpin the insights of this paper, we cannot escape the underlying (fortunate) problem that crises are rare. Results, therefore, have to be interpreted with some caution.

These formal statistical tests confirm the insights from the raw data and previous work.

The total DSR and the credit-to-GDP gap, two indicators traditionally used as BIS EWIs, have the highest AUCs across all forecast horizons (Table 1, top two rows). While there is no statistically significant difference between their information content, the aggregate DSR has the highest AUC for the short horizon and the credit-to-GDP gap the highest AUC for the longer one. This confirms earlier findings [Drehmann and Juselius (2012)]. In line with the results from Figure 1, the property price gap performs particularly well around two years before crises, but it becomes uninformative in the pre-crisis year, when it tends to decline or close.

Household debt indicators, in particular the household DSR, are also informative (Table 1, fourth and fifth rows). Based on the AUC point estimates, the household DSR performs even slightly better than the aggregate credit gap in the pre-crisis year. It also outperforms the household credit-to-GDP gap, which we will, therefore, not consider in the rest of this article.¹⁵

¹⁵ Strictly speaking, the household credit-to-GDP gap performs marginally better than the household DSR for quarters 10 to 12. These differences are not statistically significant. Still, we drop the household credit-to-GDP gap because it becomes uninformative in the pre-crisis year.

Confirming what policymakers have long stressed, international debt also contains useful information (Table 1, last two rows), although on balance not as much as the aggregate and household debt indicators. AUCs for the cross-border claims indicator are statistically significant but lower than those of the top-performing indicator, even though statistically it is hard to distinguish between the two. The foreign currency debt indicator does not perform as well as the traditional indicators throughout. To simplify the analysis, in what follows we retain only the indicator based on cross-border claims.

We next operationalize the indicators for policymaking, based on the chosen threshold criteria (Table 2). We show the values of the noise-to-signal ratio for different indicators subject to predicting correctly two-thirds of the crises. The left- and right-hand panels show the EWIs' performance over the longest available sample and over a smaller common sample, respectively.¹⁶

The analysis confirms that the household DSR adds value. It has the lowest noise-to-signal ratio across all indicators and samples. A 1.4 percentage point positive deviation of the household DSR from its long-run average captures around 70% of crises with a noise-to-signal

ratio of roughly 20% across the two samples, i.e., one false crisis call for every five correct ones. This result is not only driven by the GFC: the household sector DSR also exceeded this threshold in four out of the six crises before 2000.

In terms of noise-to-signal ratio, the performance of the cross-border claims indicator is roughly equivalent to that of the credit-to-GDP gap, regardless of the sample considered. However, the credit-to-GDP gap predicts a larger percentage of crises.

The comparison of noise-to-signal ratios should not, however, be overemphasized. For instance, the somewhat higher noise-to-signal ratio of the credit-to-GDP gap is mainly due to its tending to signal crises very early, some five to seven years ahead of the event [Drehmann et al. (2011)]. While these are “wrong” signals according to our formal criteria, they nevertheless still correctly identify the build-up of vulnerabilities.¹⁷

Table 2 also highlights the EWIs' robustness. Despite large differences in sample size between the longest and the smaller common sample (left-hand panel versus right-hand panel), the thresholds for each indicator are

Table 2: Optimal signaling thresholds for standalone EWIs

EWI	ALL AVAILABLE DATA ¹				COMMON SAMPLE ²			
	Threshold ³	Predicted ⁴	NTS ⁵	# crises ⁶	Threshold ³	Predicted ⁴	NTS ⁵	# crises ⁶
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
	At least 66% of the crises predicted							
HOUSEHOLD DSR	1.4	68.4	18.7	19	1.4	68.4	22.7	19
TOTAL DSR	1.8	67.9	22.4	28	1.8	68.4	24.2	19
CREDIT-TO-GDP GAP	9.0	80.0	25.7	30	9.0	78.9	32.6	19
CROSS-BORDER CLAIMS TO GDP	34.0	72.4	27.3	29	34.0	68.4	31.2	19

¹ Results are based on the broadest data coverage for each indicator.

² Results are based on a common sample, when all four indicators are available.

³ Optimal EWI threshold that minimizes the noise-to-signal ratio while capturing at least 66% of the crises. In percentage points.

⁴ Percentage of correctly predicted crises. A crisis is judged to be correctly predicted if the indicator variable breaches the critical threshold (column 1 or 5) anytime within a three-year horizon before a crisis.

⁵ Noise-to-signal (NTS) ratio; fraction of type II errors (the threshold is breached but no crisis occurs within the next three years) divided by the fraction of correctly predicted crises (column 2 or 6). ⁶ Number of crises included in the analysis.

Sources: IMF, International Financial Statistics; national data; BIS credit to the non-financial sector, debt securities, locational banking and property price statistics; authors' calculations.

¹⁶ Tables A2–A6 in the online appendix, available from the authors, show the results from a broader range of thresholds in addition to the one that minimises the noise-to-signal ratio subject to predicting 66% of crisis.

¹⁷ Regardless of the sample, Table 2 identifies a critical threshold for the credit-to-GDP gap equal to 9 for the requirement of predicting at least 66% of the crises. This is fully in line with previous findings. It is also consistent with the Basel III calibration, which suggests that the countercyclical capital buffer should be at its maximum if the credit to GDP gap exceeds 10 [BCBS (2010)].

identical in both cases. This shows that the results are not solely due to advanced economies or crises related to the GFC – two key features of the common sample. The main insights from the table are also robust to performing bivariate comparisons for each possible pair of indicators.

5. COMBINED INDICATORS

Previous work has shown that combining information from credit and asset markets into composite indicators can improve performance. This is intuitive as financial booms feature both exuberant credit growth and buoyant asset prices. Given the role of housing as collateral, the literature has highlighted in particular how residential property prices amplify the financial cycle, despite their inferior performance as standalone indicators (Table 1).

Thus, we next derive optimal thresholds for combinations of debt variables and property prices. We follow the same logic as before. But for a warning signal to be issued we now require that (i) the debt indicator has breached

the threshold and (ii) the property price gap was above 11 within the 12 quarters preceding the breach. We choose 11 because it is the standalone critical threshold obtained for this variable based on predicting at least two thirds of the crises.¹⁸

The condition for property prices is deliberately backward-looking. As discussed above, property price growth tends to slow from very high rates ahead of crises, so that the gap closes (Figure 1, right-hand panel).¹⁹ If we were to require that both credit and property price gaps exceed critical thresholds simultaneously, the combined signal would start to “switch off” in the late stages of the boom.

Combining information from credit and property markets improves the EWIs’ precision considerably (Table 3). Noise-to-signal ratios fall below 21%, to as low as 11.8%.

The combined EWIs also lead to lower critical thresholds for the debt indicators. This is intuitive, since the information contained in property prices underscores the signal issued by rapid credit expansion, so that the threshold can be lower.

Table 3: Optimal signaling thresholds of combined EWIs: credit and residential property prices

EWI	THRESHOLD ¹ (1)	PREDICTED ² (2)	NTS ³ (3)
HOUSEHOLD DSR	0.5	68.8	12.1
CREDIT-TO-GDP GAP	4.0	68.2	20.9
TOTAL DSR	0.4	66.7	11.8
CROSS-BORDER CLAIMS TO GDP	19.0	70.0	19.0

¹ Optimal threshold that minimizes the noise-to-signal ratio while capturing at least 66% of crises. In percentage points.

² Percentage of correctly predicted crises.

³ Noise-to-signal (NTS) ratio; fraction of type II errors (the EWIs signals a crisis but no crisis occurs within the next three years) divided by the fraction of correctly predicted crises (column 2).

⁴ The percentage of correctly predicted crises and the noise-to-signal ratio are based on joint signals that also incorporate information from property price gaps. A crisis is judged to be correctly predicted if (i) the debt indicator variable breaches the critical threshold (column 1) anytime within a three-year horizon before a crisis and (ii) the property price gap exceeds 11 at some point in the 12 quarters preceding the breach of the debt indicator variable.

Sources: IMF, International Financial Statistics; national data; BIS credit to the non-financial sector, locational banking and property price statistics; authors’ calculations.

¹⁸ Simultaneously changing thresholds for the debt indicators and property price gaps leads to even lower noise-to-signal ratios. But it complicates the interpretation across debt indicators for vulnerability assessments such as Table 4. As an alternative method to ensure a common property price gap across the debt indicators, we also searched for the optimal threshold for the property price gap if we minimize the average noise-to-signal ratios of the combined indicators, conditional on a common property price gap threshold for all of them. This does not deliver significantly different results.

¹⁹ We also tried to capture the intuition from the graph by requiring not only that the property price gap is above the critical threshold in any of the previous three years but also that its current change is negative. This did not modify the forecast performance much.

²⁰ Provided in Tables A2–A6 in the Online Appendix, available from the authors.

6. ASSESSING CURRENT VULNERABILITIES

What do the EWIs suggest about current vulnerabilities? Table 4 takes a closer look at the status of the various indicators as of June 2017, while Section 6.1 provides a short discussion of how to use and interpret EWIs more generally.

The color coding is based on the standalone indicators (Table 2). Cells are marked in green if the indicator has breached the threshold for predicting at least two-thirds of the crises. Those marked in amber correspond to the lower threshold required to predict at least 90% of the crises.²⁰ This avoids a false sense of precision and captures the very gradual build-up in vulnerabilities. Asterisks indicate that the corresponding combined credit-cum-property price indicator (from Table 3) has breached its critical threshold.

The picture that emerges is a varied one.

Aggregate credit indicators point to vulnerabilities in several jurisdictions (Table 4, first two columns). Canada, China, and Hong Kong SAR stand out, with both the credit-to-GDP gap and the DSR flashing green. For

Table 4: Early warning indicators for stress in domestic banking systems

U.S.	-6.9	-1.1	-1.5	-15.2
LEGEND	Credit/GDP gap \geq 9	DSR \geq 1.8	DSR \geq 1.4	XB claims \geq 34
	4 \leq Credit/GDP gap $<$ 9	0.1 \leq DSR $<$ 1.8	0.6 \leq DSR $<$ 1.4	18 \leq XB claims $<$ 34

The threshold for green (amber) cells minimizes false alarms conditional on capturing at least two-thirds (90%) of historical crises with a cumulative three-year prediction horizon (see Table 2 and Tables A2–A6 in the Online Appendix, available from the authors). Asterisks highlight a signal of the combined indicator when property price gaps were above 11 at some point during the last three years (see Table 3).

¹ Simple average of CZ, HU and PL.

Sources: IMF, International Financial Statistics; national data; BIS credit to the non-financial sector, locational banking and property price statistics; authors' calculations.

Canada and Hong Kong, these signals are reinforced by property price developments. The credit-to-GDP gap also flashes green in Switzerland, whereas the total DSR flashes green in Russia and Turkey. Credit conditions are also quite buoyant elsewhere. Credit-to-GDP gaps and/or the total DSR send amber signals in some advanced economies, such as France, Japan, and Switzerland, as well as in several emerging market economies (EMEs). In Indonesia, Malaysia, and Thailand, as well as some other countries, property price gaps underscore this signal.

Some jurisdictions also exhibit some signs of high household sector vulnerabilities. In Korea, Russia, and Thailand, the household sector DSR flashes green (Table 4, third column). In Thailand, the green signal for the household DSR is underlined by the property price indicator. Property prices have also been elevated in Sweden and Canada, which exhibit an amber signal for the household DSR.

The cross-border claims indicator supports the risk assessment for several countries and flags some potential external vulnerabilities for others (Table 4, fourth column). The indicator flashes green for Norway and is amber for a number of economies.

While providing a general sense of where policymakers may wish to be especially vigilant, these indicators need to be interpreted with considerable caution (see also section 6.1). As always, they have been calibrated based on past experience, and cannot take account of broader institutional and economic changes that have taken place since previous crises. For example, the much more active use of macroprudential measures should have strengthened the resilience of the financial system to a financial bust, even if it may not have prevented the build-up of the usual signs of vulnerabilities. Similarly, the large increase in foreign currency reserves in several EMEs should help buffer strains. The indicators should be seen not as a definitive warning but only as a first step in a broader analysis – a tool to help guide a more drilled down and granular assessment of financial vulnerabilities. And they may also point to broader macroeconomic vulnerabilities, providing a sense of the potential slowdown in output from financial cycle developments should the outlook deteriorate.

6.1 What do EWIs tell us?

This section explains how to read the table that assesses current vulnerabilities based on the set of early warning indicators (EWIs). Then it explains the limitations of those indicators in the context of a broader analysis of vulnerabilities,

To interpret the table entries, it helps to understand the methodology used to derive the critical thresholds that – if crossed – lead to a warning signal. For any indicator, we start off with a large sample spanning countries and time that ideally contains as many crises and non-crisis periods as possible. After checking whether the indicator has more EWI power than a coin toss,^① we search over a range of potential thresholds that, when breached, issue a warning signal. We judge a crisis as correctly predicted if there is a warning signal at least once in the 12 quarters preceding the crisis, i.e., if the crisis occurs anytime within the three years following the breach. If a signal is issued but no crisis occurs within that time frame, we count this as a false alarm.

We choose two different thresholds to identify amber and green “alert zones”. In both cases, the calibration, drawing on historical experience, minimizes the ratio of false alarms to correct warning signals (the “noise-to-signal ratio”). But one threshold is chosen so as to predict at least two-thirds of the crises (green), and the other at least 90% (amber). The green threshold is more stringent (higher) in the sense that it is exceeded less often.

The cells also include asterisks (*). These refer to instances in which the combined behavior of the corresponding debt and property price indicators signal vulnerabilities. For this debt-cum-property price combined indicator we follow a similar logic to the one above. We keep the property price gap threshold constant at its optimal standalone value and then optimize over the debt indicator threshold, so as to capture at least 66% of crises while minimizing the noise-to-signal ratio. In other words, for a warning signal to be issued, we require that (i) the debt indicator breached the critical threshold and (ii) the property price gap was above 11 (the green threshold for the property price gap on its own) within the three years before the breach.^② When this happens, we add an asterisk to the relevant EWI.

To interpret these signals correctly from a statistical viewpoint, a few points are worth recalling:

- Over the calibration period, there were naturally many instances in which the indicators breached the thresholds (corresponding to signals denoted by the amber, green, and * identifiers) but crises did not materialize within the following three years. The more often this happens, the higher the noise-to-signal ratio.
- This may happen because crises do not materialize at all: the indicator subsequently switches off and imbalances correct themselves. Alternatively, it may happen because the signals may occur “too early” (e.g., five or six years before a crisis), with the indicator correctly continuing to signal risks until the crisis breaks out.^③ In general, even when the indicators identify the risk of crises correctly, it is unrealistic to expect them to identify the timing with any precision.
- Noisy signals also mean that the statement “66% of crises were preceded by a breach of the EWI threshold” is not equivalent to “the crisis probability is 66% once the threshold is breached.” Or putting it differently, the former statement says that “given that a crisis has occurred, the threshold was breached in 66% of the cases”; the latter means “given that the threshold is breached, a crisis occurs in 66% of the cases.” The reason the two statements are not equivalent is that some breaches do not herald crises, i.e., the noise-to-signal ratio is higher than zero. In fact, in our sample and as a rule of thumb, the likelihood of a crisis emerging once the threshold for an indicator is breached is around 50%.^④

More generally, certain caveats need to be borne in mind:

- EWIs have only two settings: “on” or “off”. They do not reflect the gradual intensification of a financial boom. (The use of two thresholds is designed to capture this to some extent.)
- The exact thresholds should not be overemphasized. We have run a battery of checks and drawn on other research to make sure our economic insights are as robust as possible. But the exact optimal thresholds identified can vary by a few percentage points across specifications. Given these uncertainties, whether an indicator is just above or below a threshold is not a first-order issue for monitoring purposes.
- EWIs are based on historical relationships. Thus, structural breaks may reduce their predictive power, e.g., as a result of increased use of macroprudential

measures or changes in prudential regulation more broadly. This is only partly mitigated by evidence indicating that similar variables have displayed consistent predictive power going back to at least the 1870s [Schularick and Taylor (2012)].

- EWI thresholds are common across countries. Thus, they cannot take into account country-specific features. This is inevitable: as crises are rare events, it is not possible to calibrate the indicators with any statistical confidence based on the experience of any individual country.
- The EWIs displayed in the table are specifically designed to capture only vulnerabilities linked to the financial cycle. Other vulnerabilities that could lead to banking crises are not considered (e.g. sovereign crises owing to unsustainable fiscal positions).

Taken together, these caveats suggest that EWIs cannot be analysed in isolation. They are best seen as a useful starting point for a more granular assessment of vulnerabilities.²¹

7. CONCLUSION

This article has formally assessed the performance of household and international debt as EWIs for banking distress. These variables are found to contain useful information about banking system vulnerabilities, similar to that of their more widely used counterparts based on aggregate debt. Within the group of household-based indicators, the household debt service ratio stands out. Within that of international debt indicators, cross-border claims perform better than foreign currency debt.

At the same time, in assessing these results it is also important to take into account data limitations. Crises are rare events even in samples where data coverage is good. And they become “rarer” for samples over which we can consider household or foreign currency debt. This prevents a more detailed, robust analysis of EMEs in particular. More definite comparisons and inferences would require overcoming these limitations. Thus, improving the data is an area that deserves greater attention.

²¹ ① Formally, we test whether the AUC is statistically significantly different from 0.5.

② We use backward-looking information for residential property prices, as the associated gaps tend to close ahead of crises (Figure 1).

③ For instance, this is the case for the credit-to-GDP gap [Drehmann et al. (2011)].

④ The derivation of how likely a crisis is given an EWI signal is much more sample-dependent than the thresholds shown in Table 2 because of small sample issues.

ABOUT CAPCO

Capco is a global technology and management consultancy dedicated to the financial services industry. Our professionals combine innovative thinking with unrivalled industry knowledge to offer our clients consulting expertise, complex technology and package integration, transformation delivery, and managed services, to move their organizations forward. Through our collaborative and efficient approach, we help our clients successfully innovate, increase revenue, manage risk and regulatory change, reduce costs, and enhance controls. We specialize primarily in banking, capital markets, wealth and investment management, and finance, risk & compliance. We also have an energy consulting practice. We serve our clients from offices in leading financial centers across the Americas, Europe, and Asia Pacific.
